Economic Power and New Business Models in Competition Law and Economics: Ontology and new metrics

Abstract:

European systems of competition law employ the concept of dominance, which has evolved to a unified conceptual framework and has framed the texture of competition law enforcement. This aims to measure the degree of dominance of a firm from established or potential rivals on a specific relevant market and focuses on the price dimension of competition.

The digital economy challenges this conceptual framework. New business models rely on zero-price markets and multi-sided platforms, while competition authorities try to grapple with the broader concern over the bargaining power of large digital platforms and the rise of gatekeepers in the digital economy. These developments have culminated in the recent calls for a more multidimensional concept of (economic) power, in particular in the context of competition law enforcement against unilateral conduct². Without aiming to present an exhaustive list, various concepts have been put forward as a trigger for regulatory/competition law intervention, such as strategic essential facilities³, essential facilities⁴, essential facilities⁵, and essential facilities⁶. These may complete, or even substitute, the archetypical concept of market or monopoly power in competition law, which is determined in the context of a specific relevant market.

The multiplication of new concepts of power signals the creativity and flexibility of the competition law enterprise as it seeks to take into account new economic realities. Business models recognize the strong cross-side effects of multi-sided platforms. Platform business models are not geared towards a stable and well-defined final product (eg an automobile), but dynamic in themselves, easily moving sectors and adding new ones to the portfolio (eg e-commerce platform engaging also in financial services). This is significant as economic power is not necessarily manifested in the context of a final product market (not necessarily a final product) but accounts for a process of cross-market activity and cross-market capabilities. This brings into light that traditional conceptions of power and related indicators are insufficient to capture all the dimensions of economic power that are more prominent in these new business architectures that characterise modern digital and non-

² See, CERRE, Making Economic Regulation of Platforms fit for the Digital Age 6

digital ecosystems. The concept of ecosystem reflects the emergence of business environments marked by modularity in production, co-evolution, and decisional complexity, where innovation must be coordinated across different hierarchies, markets, and industries⁷. They form ökpvpkpcn eqo o wplkguö qh geqpqo le cevtu y j q vq c rcti g gzvgpveq-evolve their goods and services with cni pgf xkukpu cpf õy j qug kpf kkdual business activities share in some large measure the fate of vj g y j qng eqo o wplk(ö⁸. The motivation of the paper is therefore to contribute to the understanding and measurement of these new dimensions of economic power.

We start from the premise that if left untheorized, this trend will generate conceptual incoherence and legal uncertainty. One possible strategy to overcome this problem is to attempt to define precisely the specific field of each of these conceptual categories of power and address any overlaps that may exist between them. Hence, once the field of intervention of each concept, and its necessary elements (their ontology), is delimited, it would be possible to

to competing with firms in the same relevant market and/or potential horizontal competitors at each segment of a value chain, there is also vertical competition among the firms forming part of the same value chain or which have a complementary relation in the context of an ecosystem as to which one will be able to capture the largest share of the surplus value generated by the value chain or the ecosystem. This is particularly relevant in digital ecosystems, where the creation of wealth is mostly generated through higher market valuation by financial markets, which due to their emphasis on futurity, realize that holding certain assets or gatekeeping positions and developing specific competitive strategies will bring a sustainable architectural competitive advantage for the specific firm¹¹.

The framework should also integrate competition from complementary technologies that may challenge the lead position of incumbents in a value chain or an ecosystem (vertical innovation competition). Competition economics has largely focused on horizontal competition from established competitors (producing substitute products), or on the threat of entry of potential

welfare, this joint surplus will be split between the benefits (net of direct costs) each participant receives. Each participant in a joint project should therefore receive benefits at least as great as in their next best alternative, so as to maintain their incentive to participate to the joint project (the so called participation constraint).²⁶ If all participants in a cooperative project are satisfied, the question of distribution is settled in an economically efficient way.²⁷ What matters is not the distributive outcome as such, for instance that each participant enjoys an equal share of the joint profit, but the fact that each participant has been able to get a payoff equivalent to their next best alternative. Absent this rent from the joint surplus collected by the participants, these will have no incentive to enter into the joint activity at the first place.

It is possible to imagine that a single participant could gain the most important part of the joint profit if, for instance, he makes take-it or leave-it offers to the rest of the participants that are only net of the joint surplus.²⁸ To the extent that the joint surplus is net of the joint profit, this outcome is economically efficient. However, this outcome may not be considered fair to the extent that it leads to an unequal allocation of the joint profit, should one consider that fairness requires that the joint surplus produced is to be allocated equally between the participants.

However, such broad distributive justice concerns are difficult to integrate in competition law analysis, unless one focuses on easy to handle quantitative proxies of process-based economic power, such as the turnover or number of users/eyeballs of a digital platform, as is the case in the recently proposed Digital Markets Act (DMA)³⁰, to the extent that it can be assumed that such properties (large size) will affect the bargaining process. However, this will require the determination of specific quantitative and qualitative criteria that would define the specific properties of the participants to the bargaining process.

These can be legally determined by the legislator, and preferably set following a careful impact assessment process. In the DMA Proposal (Article 3), gatekeepers are defined as entities that (i) have a significant impact on the EU internal market, (ii) operate one or more important gateways to customers, and (iii) enjoy or are expected to enjoy an entrenched and durable position in their operations. The DMA definition is intended to apply to a particular dominant actor, where economic significance, scope, or size provide pragmatic grounds for concern about control over a significant part of the economy. The DMA refers to certain quantitative criteria that establish a presumption for the gatekeeper status (see Table 1), thus establishing ex ante the properties of the undertaking(s) to which will be imposed specific regulatory duties.

o wwwnf gr gpf gpeg, qt vj g uwo qhvj gkt f gr gpf gpeg⁵¹. This needs further elaboration, taking into account that social exchange theory does not analyze the resource differential linked to the kpf kxf wnej ctcevtkueu qhvj g cevqt kp cdutcev, dweqpegkxgur qy gt cu c ÷ tqr gtv\ qhvj g uqekn tgrvkpp⁵². Blau has indeed observed that exchange relations between a person or entity with another may take different forms: (i) independence (if the outcomes of the exchange depend on qpgø uqr ghhqv), (kk) f gr gpf gpeg (kh vj g qweqo gu f gr gpf qp vj g qvj gt gpvk\ øu ghhqv cpf (kk) interdependence (the outcomes are based on a combinatiqp qhvj g r ctvgtuø ghhqv)⁵³.

social structure of the exchange, in particular the position of the specific entity in the social network to which it belongs (routines). Power as potential is not only a function of the position of the actor in the network, but also of the position of the other actor in the network⁵⁹. Similarly, others have focused on the network position of the economic actors in order to determine the power-dependence not in the context of a dyadic relation, but in the context of a network⁶⁰.

Taking a sociological perspective, Cook et al. focus on social structure as a possible source of power. Social structure is defined as a configuration of social relations and positions among actors (the network structure, the position of the actor in the network, the position of the other actor in the network, etc.)⁶¹. These relations are not only linking actors directly, but also indirectly⁶². An exchange relation may thus not only occur directly between two actors, but could

o wkrvgtcn, pqpigpgle eqo r ngo gpvctkku vj cv ctg pqv hwnf j lgtctej kcmf eqpvqmgf⁷⁹ shows that, like value chains, they always entail positive connections. However, firms within ecosystems can coopete (compete and cooperate simultaneously)⁸⁰, For example Google News and news publishers cooperate in that they are vertical complements: pgy u r wdrkuj gtuo eqpvqpv j gr u attracting users to Google News (positive connection: without news publishers Google News cannot exist)

o ctngwy kj rcti gt eqpegpvcwp tcvku⁸². Hendrickson and James provide the following example drawing on different market configurations: assuming a market with a CR4 of 80 with the four firms holding respectively 77, 1, 1, and 1% and a market with a CR4 of 100 with each of the four firms holding a 25% market share, they argue that the market with a CR4 of 80 will create higher dependency than the market with the CR4 of 100⁸³.

Focusing on resource dependence in the context of a dyadic exchange relation or a network has also some implications on the conceptualization of power. This is not anymore linked to the exceptional ability of an actor to raise prices, reduce output, as is assumed in the horizontal power approach, or to exclude rivals, as in the context of bottleneck power, but focuses on the way in which the value in the exchange, dyadic or at the level of the network or organization, is divided between the different actors. The way the value is divided results from the unevenness in dependencies between actors. In that respect, social exchange theory can subsume bottleneck power and the traditional horizontal power approach as particular cases. Power will in this case

ppg vngu c o gtkuø dcugf cr r tqcej v j cv y qwf xcnwg uw r gtkqt eqo r gkkxpgguu cpf ghlekpe{. Determining if an allocation of resources is fair has been the subject of intense controversy among scholars in various disciplines and its lessons for competition law have been examined elsewhere⁸⁷.

Power could thus be conceived as differential dependencies that do not rely on its outcome (distribution of surplus) because otherwise the (positive) assessment of the level of power would depend on the (normative) judgement of which distribution of uwtrnwu ku eqpukf gtgf -dcktoø something that opens up a broader debate on the policy premisses and the social function of competition law.

2.2.4. Different dimensions of positional power

2.2.4.1. The concept of positional power: an introduction

As explained in the previous Section, a uqekncexvtøur qy gt f qgu pqvqlhgp tgrvq v j ku kpf kxf wcn characteristics and exceptional attributes, but may also be function of the network structure, to the extent that this actor holds a pivotal position in the underlying social structure of the exchange. In xkgy qh -the tendency of complex systems to create asymmetric network structures, in which some pqf gu ctg -j wdu,øcpf ctg hct o qtg eqppgevgf v j cp qj gtuø it is essential to examine the topography of such complex systems⁸⁸. Centralised networks provide actors with the necessary levers to extend their influence and thus reach sooner the tipping point towards sustainable dominance, eventually using the networks for their own purposes rather than those that led to the formation of the network at the first place. Centrality measures, such as degree centrality (where the node strength gives a measure of local influence), betweenness centrality (the amount that a node lies on shortest path between other nodes) and closeness centrality (inverse sum of shortest distances), which measure centrality at the level of a specific node, are indeed the most commonly used indicators in order to assess the importance of an actor in a network⁸⁹.

The greater the centralization of a complex system, such as a network or an ecosystem, the rcti gt v j g f kur ctkv dgw ggp v j g pqf guø kpf kxf ual centrality measures. Degree centrality simply counts the number of connections a node has (in terms of potential communication activity): those with a high degree of centrality are more active players. The distribution of degree centrality among the nodes of a network may indicate how equal network actors are.

pgv qtmo c{ i ckp hqo vj gk r quklp vj tqwi j -dtqngtci gø⁹². One may think for instance of actors such as platforms bringing together various users in multi-sided markets may have a high betweenness centrality without necessarily having a high degree centrality. A node that connects two separate networks may have a low degree centrality but may be highly influential if it sits on the only path through which the nodes of the two networks may reach each other⁹³. However, if there are multiple geodesis paths that may connect the two networks the node will not have a high betweenness centrality. Having a high central point often exhibit potential for control of the network.

Hkpcmf, -emugpguu-baugf o gcuwtguø r tqxkf g an index to the extent that a particular point is closer to another, by measuring how fast a given node in a network can reach other nodes. The clique is characterised by the mutuality of ties between its members, all of which, in the narrow definition of a clique, are directly connected to each other with no other node in the network having ties to every member of the clique⁹⁷. The members of the clique have frequent interactions with each other, as opposed to interactions between the members and outsiders.

These concepts enable researchers to visualize the way a network unfolds and to determine the centrality of a node, according to the prevailing definition of centrality, with the assistance of visualization tools, such as multidimensional scaling (MDS).

We have previously explored how power may be linked to dependence in an exchange relation, and the way exchange theory may be implemented beyond the situation of a dyadic relation. According to the power-dependence perspective, the dependence of one actor on another is a function of the interest in the resource that actor has and the availability of that resource from alternative sources⁹⁹. These alternative resources may be other nodes in a network, or a structure of connected social actors.

These approaches may nevertheless constrain strategic action to bargaining within existing network configurations, and ignore the possibility that the actor may negotiate changes in the

network itself. Leik explains how it is possible for an actor to gain power through manipulating the linkages of the network, $\int w_i c_i \pi_i \int g r q y g t r q g p k n q h q p g o r q u k q p^{100}$

To the extent that one emphasizes social interactions along the lessons of social exchange theory in order to define a broader ontology of power, it becomes important to acknowledge various other dimensions than the one that has been the traditional focus of competition law and economics, market power or power over price and output. This is particularly important in view of the new business models in the digital economy, but also beyond, that generate market value through advertising revenue in attention markets combined with zero-priced services in a multi-sided markets context and the constitution and exploitation of business ecosystems. Focusing only on output and price does not take adequately into account the importance in such contexts of complex value creation and monetization strategies that impact on other parameters of competition (e.g. quality) and involve multiple spaces of competition and forms of value capture (e.g. in financial markets through asset-stocks re-evaluation).

2.2.4.2.1. Power based on the control of the agenda/discourse

Grannovetter distinguishes economic power based on dependence from economic power based on legitimacy; to the extent that someone occupies a position of legitimate authority and thus holds the power to command, while others the duty to obey¹⁰⁵, and economic *power based on control of the agenda/discourse*, the latter being particularly effective in view 4(nd)] Tjf-o(d o)-9(n th)] Tjf-o(d o)-9(n th)]

Panopticon power results from the position of an actor in a network and is not related as such to the existence of some form of dependence. It is possible that the different actors in a network voluntarily agree to share information through the hub, for instance because they trust it better than directly communicating between them, or because it is more convenient to do so. As each of these nodes is not dependent on the hub, in the context of a dyadic relation the hub cannot be considered as holding power over them. However, this conclusion changes if one takes into account the fact that the actor also serves as a hub for a number of other interactions which provide that actor some superior and more complete information on the strategies of the other members of the network, including its adversaries, if the latter enter into communication interactions with some of the nodes also communicating with the hub.

These findings are particularly important in view of the prevalence of business strategies to

this stability, such as the requirement for any new technology to be interoperable with the technical standards of the industry architect who benefits from an installed base, the quality certification barrier from which the industry architect benefits as it may have been framed so to respond to the risks generated by the technology of the incumbent or to accommodate the needs of the industry architect. This shift from the dyad to industry-wide networks of relationships regarding the allocation of the financial returns of innovation also explains the reason for the competitive game being more complex and wider than the usual focus of competition law on a relevant market.

Various factors may influence industry architecture. One is technological path dependence which results from a self-reinforcing process triggered by an event, such as a first mover advantage from a quality of technology perspective, equilibrium, without that being the intention of the agents at the first place¹¹². The legal/ regulatory framework may also play a crucial role in the definition of the boundaries of an industry and of its governance. Quite often it supports the existing industry architecture. Firms, however, may use strategies seeking to manipulate the industry architecture so to create a bottleneck and to maintain it by suppressing through mergers and/or exclusionary conduct any strategies of ecosystem differentiation by competing industry architects with the aim to develop close but distinctive competitive alternatives that may provide complementors and/or consumers the opportunity to break their lock in with the specific ecosystem. The firm controlling the bottleneck is also in a position to extract all surplus value in the specific segment as well as a higher percentage of the surplus generated by innovation in vertically adjacent segments. This may take different forms, such as manipulating the setting of technology standards as often standards shape industry architecture or influencing the regulators and/or the legislative framework shaping the architecture

companies that collaborate with them in the creation of surplus value¹¹⁶. The concept of
a hypothetical space where intra- and inter-industry competition occurs¹¹⁷.
Hence, to understand this process of value extraction that motivates strategies of competition, it is
important to examine power both at the market level and the indus

Table 2: The Multiple Dimensions of (Economic) Power

| Power family | Type of power | Source of power | Modality of power exertion | Scope of power sourcing exertion in an economic context | Existence of standard metrics or modelling in competition law |
|---------------|---------------|---|---|---|--|
| Coercion | Coercion | Capacity to influence other actors' conduct and/or to affect outcomes directly in the context of a bargaining process | Absence of alternative "reasonable choices" | Value chain/ecosystem and horizontal | No (because the concept is either too broad or too subjective) |
| Process-based | Process-based | | | | |

As Table 2 summarizes from the previous discussion, there have been developments regarding the concept of (economic) power to capture power exertion beyond horizontal competition within a relevant market. However, for different reasons, not all of these concepts have been translated into metrics that could be used by antitrust authorities and regulators. Although interesting to understand many economic dynamics, coercion power remains too broad to be translated into a metric. Process-based, exclusionary/bottleneck and architectural power, in turn, are contextual. Hence, no single metric can be established to measure these types of powers within any given ecosystem/value. Applying these types of power to antitrust cases or to derive regulatory measures requires therefore to rely on contextual behavioral evidence. Finally, power based on differential dependency between value co-creators (social exchange theory) and panopticon power could be translated into metrics that could be applied across different ecosystems or value chains. In the next section we turn to this endeavour.

3. Metrics of value chain or ecosystem-level vertical economic power

Competition law has developed advanced quantitative tools to measure horizontal power (market power), which are frequently employed in competition law analysis. This has not occurred yet for the various theories of vertical power examined in the previous Section. The review of theories of power in Section I has shown that they can be divided in two groups in terms of the scope of power: vertical and/or horizontal power theories. These theories (coercion, process-based, standard market power and exclusionary/bottleneck) describe situations in which power originates in and is exerted at the immediate vertical (i.e. suppliers or clients) or horizontal (competitors within the same market) level. Value-chain-level and ecosystem-level theories. In these theories, the structure and the characteristics of the ecosystem or value chain (i.e. the network in which economic agents co-create value) of value creation affect power allocation between its members. Moreover, the latter can exert power over other members of the ecosystem/value chain even when they are not located in the immediate upstream or downstream tier or when they are not direct competitors within a market by obtaining a higher share of the value created within the value chain or ecosystem.

As mentioned above, social exchange theory and panopticon theories of power have not been translated into metrics that can be used in the context of competition law and economics. In this section we intend to contribute to bridging this gap. In particular, we will provide metrics of value chain/ecosystem-level power originating in differential dependency (social exchange theory) and unequal information gathering (panopticon) between the firms of a value chain or ecosystem. As mentioned above, we will not address value-chain-level and ecosystem-level theories of power, architectural power, as its functioning responds to long-term institutional, technological and social transformations that cannot be at present translated into metrics.

3.1.A metric of resource-based value chain or ecosystem-level power based on differential dependency

We have seen in subsection 2.1.2.3 y cvc hto of hgt gpcnf gr gpf gpe{ y kj k c network

a two-dimensional space (i.e. as lines on a plan) on which firms (nodes) are contained. Figure 1 illustrates this.

Figure 1: A value chain with one upstream supplier

In Figure 1, nodes represent firms and the lines that surround them represent the technical and institutional conditionings affecting the value chain. In this example, the combination of technical and institutional conditionings (i.e. industry architecture) leaves room for only one firm to exist downstream in the supply chains that can be formed. An example of this can be railway transportation in many European countries, where high fixed costs of having deployed already-existing networks (technical conditioning) and the decision of antitrust agencies to have competition on infrastructure (institutional conditioning) created a monopoly upstream (Cayla, 2014). Technological progress that reduces the high fixed cost of deploying a network or a change in antitrust policy to create competition through infrastructure can be represented by a loosening in the lines that surround the upstream node (firm), opening the possibility to the existence of more firms upstream. Then, changes in any of these two conditionings affect the number of firms in each tier, the scope of their possible vertical integration and the possibility of relating to each other¹²¹. In terms of Jacobides, Knudsen and Augier (2006), v_j g π wgt ctg v_j g δ vgej p κ crö cpf öngi cncpf tgi w ν qt { cwj qtk { ö f gvtö kpcpv qh kpf wut { ctej kgewt gu¹²².

If a central firm was to leave the value chain, the value of the latter would be greater than if a non-central easy-to-replace firm left (Crook & Combs, 2007). Dgecwug öc pqf g] hto _ with high betweenness centrality has a great capacity to facilitate or constrain interactions between

to function because they perform tasks and/or handle a considerable volume of transactions (sales, user traffic, etc.).

simple market share when assessing a firm's dominance within a value chain or ecosystem. Let us illustrate this with an example.

Figure 2: Network of sales/purchases between Greek suppliers and supermarkets for the pasta product category in 2019

As Figure 2 shows, supplier 63 concentrates most (55%) of vertical power in the value chain. The second firm in terms of vertical power is supplier 1 with a SSBC indicator level of 21%. This contrasts with its market share of 36%, which would fall short of European Co

soft drinks from supermarkets to suppliers in 2018. The same graphic interpretations and underlying calculations employed for Figure 2 apply.

Figure 3: Network of sales/purchases between Greek suppliers and supermarkets for the soft drinks product category in 2018

Supplier 21 concentrates most of the vertical market power with a SSBC indicator of 52%. However, its market share is 50% because the main buyers, supermarkets 45 and 9, are highly dependent on it to obtain their supply. Although slight, this discrepancy would have a considerable impact in the less interventionist courts of the United States, which have used a 50% threshold to establish dominance¹²⁴. A market share of 50% (49.82% to be precise) could have raised doubts regarding whether Supplier 21 is dominant. In the United States, a 50% threshold is used to establish dominance, even the less interventionist courts would conclude supplier 21 is dominant in the soft

drinks wholesale market. As this example illustrates, using the SSBC indicator can reduce false negatives when assessing dominance.

Two relevant considerations regarding the application of the SSBC indicator should be pointed out. First, the thresholds to be employed are not necessarily the same ones as those established by competition authorities in terms of market shares. While the two indicators (market share and SSBC) measure how much one side of the market (the buyer or the seller) depends on a particular firm, they do not measure the same thing. This is all the more so in cases which the indicator is not weighted by the volumes of sales. For example, the SSBC indicator could be used to assess firms' vertical power in terms of dependency on the use of a resource such as know-how, each shortest path representing a production process that requires the firm's intervention within a value chain for the final product to be built. In that respect, the comparisons between market shares and SSBC we did for the supermarkets sector should be interpreted merely as illustrations of SSBC's indicator potential to lower false negatives and false positives when assessing dominance within a value chain or ecosystem, an endeavor that would require empirically establishing thresholds that might differ from the current ones, which are based on market shares. Second, the SSBC indicator can be of particular relevance in the context of digital ecosystems, and notably those based on the monetization of data. It can be used to assess how much vertical power a firm has in terms of how much other firms depend on it for the data or their derivatives (e.g. predictions over preferences) to flow within an ecosystem. In a context in which digital ecosystems are under increasing scrutiny from antitrust agencies and regulators, there is a promising avenue for research in applying this indicator for ecosystems, as it is also acknowledged that in this context market shares are usually not indicative of firms' power¹²⁵.

3.1.2. A metric at the value chain or ecosystem level

We have just shown how the share of square betweenness centrality of a firm can be used as a metric of resource-based value chain/ecosystem-level power that draws on the concept of differential dependency. However, because this metric is firm-centric, it does not tell us what is the level of vertical power differentials within a value chain or ecosystem, a piece of information that could be useful to do a more aggregated analysis of power, especially from an antitrust perspective. Consequently, with this indicator we cannot say if there is more power concentration in a certain value chain, or ecosystem, than in another one. Therefore, in this subsection we will adapt this metric to overcome these difficulties.

vertical power is distributed within a value chain or ecosystem. It is calculated following Equation 3.

Equation 3: Vertical HHI indicator for a value chain or ecosystem with n firms

$$VHHI = \frac{\sum_{i=1}^n s_i^2}{n}$$

Then, the higher the indicator in Equation 3 is, the more imbalanced power is in the value chain, or ecosystem. This indicator would then be analogous to HHI. While the latter measures the level of market power in a market resulting from market concentration, the indicator in Equation 3 measures the level of vertical power in a value chain or ecosystem resulting from differential dependency over a resource. Moreover, since the VHHI indicator is, like the HHI, based on shares, it also ranges from 0 (total absence of vertical power imbalances) to 10 000 (absolute concentration of vertical power by one firm). However, as explained for the SSBC indicator, this does not mean that the thresholds established for HHI to assess the competitive level of a given market should apply to assess the degree of (vertical) competition within a value chain or ecosystem.

3.2.A metric of panopticon power

We have seen in sub-Section 2.2.4.2.2. that one of the positional sources of economic power, *panopticon power*¹²⁶, is based on an actor being able to benefit from its position in a network (a value chain or an ecosystem) to gather valuable information that gives it a competitive advantage. This advantage is more relevant when there is significant and growing learning-by-doing asymmetry between the actor benefitting from this position in the network and the other nodes in the network. In this subsection we will develop a metric of this type of power. In order to do so, we shall start by defining more precisely what makes information valuable and, hence, a source of competitive advantage.

Information or data¹²⁷ is valuable because of what it allows to do. Benyayer and Chignard¹²⁸ summarize what data allows to do in four verbs: describe, explain, predict and prescribe. Nevertheless, not any kind of data is valuable. In order for a dataset to allow for proper descriptions, explanations, predictions and prescriptions it needs to have certain properties, namely volume, quality and scope¹²⁹. It is important to notice that each of these three properties have a

different ponderation in making the data valuable depending on the use intended. The value of data is therefore contextual to its use¹³⁰.

Volume refers to the number of observations of the dataset. The above-mentioned valuable uses of data (describing, explaining, predicting and prescribing) rely on extracting insightful patterns using statistical techniques. As the results of the latter are more precise and robust as the dataset increases in volume, the more data there is the more solid the conclusions that can be drawn from it are. The quality of data refers to the characteristics of a dataset that make it easier to extract meaningful information from it.

The network is a multilayer network in which each of the three layers represents a tier of the value chain: vendors, retailers and final consumption. Firms are denoted by nodes (which are graphically represented as circles) and commercial transaction between them (selling/buying a good or service) as weighted directed vertices (graphically represented as arrows linking the dots). When firm A sells a good or service to firm B, the arrow goes from firm A to firm B. For every arrow (sell) going from a vendor to a retailer there is a corresponding arrow (sell) from the retailer to final consumers, as we only represent sells having taken place. The weight of the vertices represents the quality of the information embedded in the sell. Only retailers collect information from consumers and vendors. In our example we assume that retailer A obtains more information from the vendors it buys from and from the final consumers it resells to than retailer B because the former is an online platform while the latter is a brick-and-mortar store. Indeed, being an online platform gives retailer A the possibility of siphoning more data through the use of cookies that track consumer behavior, the necessary identification of individual buyers, etc. It even gives it the possibility to gather valuable consumer behavior data when consumers do not buy. Indeed, online products they repeatedly return to, what they keep in their shopping basket, and what their mouse hovers over on their website¹³⁵. Online platforms can also gather data on vendors that brick-and-mortar stores do not. For example, they can track the quality of their products, etc.

Algebraically, the

weight of the score translates the relevancy of each dimension to assess the quality of the data in the given context.

We can now define V_i in a network with n nodes out of which m nodes are information gatherers (retailers in our example).

$$= \frac{\sum_{j=1}^n}{n-m}$$

In other words, the value of the data gathered by retailer i that is attributable to volume s measured as its degree centrality regardless of the direction of the vertices, as retailers gather information from vendors and final consumers. The denominator is divided by $n-m$ (all the nodes except retailers) as retailers cannot extract information from other retailers or themselves.

Similarly, we have:

$$= \frac{\sum_{j=1}^n}{n-m}$$

In other words, the value of the data gathered by retailer i that is attributable to quality is calculated as the sum of the quality score from each transaction divided by the number of nodes out of which it could extract information.

In order to obtain a metric of panopticon power from the metrics of value of data, we divide the numerators of $ValV_i$ and $ValQ_i$ by the total volume-related and quality-related value of the data gather by all the data gatherers (retailers in our example) of the network respectively. In this manner, we obtain the shares of volume-related ($SValV_i$) and quality-related ($SValQ_i$) data value.

$$= \frac{\sum_{j=1}^n}{\sum_{j=1}^n}$$

$$= \frac{\sum_{j=1}^n}{\sum_{j=1}^n}$$

Given the context-dependent $SValV_i$ and $SValQ_i$

$$\sum_j g_j^v + Q = 1$$

Finally, we can recur to the methodology of the HHI index to build a Panopticon HHI index which is equal to:

$$- = SValVQ_i^2$$
